ABSTRACT

Most microarray image scanning approaches provide an estimation of the intensity of the foreground and background for each spot. Background intensity must be corrected in order to remove the effect of the non-specific binding or spatial heterogeneity across the array, but when such corrections are applied many problems appear, such as negative intensity for the spot or high variability of low-intensity log ratios. In this paper, many alternative methods for calculating background intensity are discussed and many approaches for background correction are tested and compared. GenePix, ScanAlyze and QuantArry are the methods reviewed for background intensity extraction. Four methods for background correction were examined and the Edwards method was found to be the best and most suitable method.

Keywords: Microarray Imaging, Background Correction, DNA, Edward Method.

1. INTRODUCTION

Gene expression regulates the production of proteins, which control all cellular processes in the human biological system. The understanding of gene expression and the mechanism of protein production has many applications in terms of diagnosis, staging and finding the suitable treatments for diseases. Using the cDNA microarray, it is possible to diagnose rapidly and efficiently the level of gene expression in the sample [1] and [2].

There are many commercial and freeware microarray analysis software packages available. Each software program can be separated into three main tasks. The first is gridding or addressing, which is the process of specifying coordinates for every spot on the slide. The second is segmentation, which classifies each pixel as either foreground, corresponding to a spot of interest, or as background, corresponding to error or noise. The third and final task is intensity extraction, which is the step for each spot on the array, calculates the green and red foreground fluorescence intensity [3], [4] and [5].

The estimation of the background intensity is a very important step to be performed as a part of the background correction process. This is because each spot intensity measure includes a contribution to the fluorescence that is not due to hybridization of the mRNA sample to produce spotted DNA. Background intensity can be estimated by more than one method, for example, using the main concentration of pixels located outside the spot mask [6] and [7].

The background correction for the spot intensity can usually be performed by subtracting the background intensity from the foreground intensity of the spot, but sometimes negative values appear where the background value is greater than the foreground value for a given spot, which seems illogical. Many studies have discussed this issue and proposed various methods that can be applied to avoid the problem [8] and [9].

The main aim of this paper is to discuss and compare the background correction alternatives and the algorithms that are used to calculate the background value pair (Rb, Gb). In this paper, several microarray background correction methods are discussed. Section 2.1 presents the existing algorithm systems for calculating the background intensity values, while section 2.2 discusses and compares different methods used for the background correction. Section 3 discusses the methodologies used in this project to correct background intensity and section 4 elaborates and compares the results of different methods. Finally, section 5, presents the conclusions.

2. LITERATURE REVIEW

2.1 Most Popular Background Intensity Extraction Methods

Most microarray analyses define foreground intensity values for red and green fluorescence (Rf, Gf) as the mean or median value of all the pixel values inside the segmented spot mask as shown by the red circle at the center. However, other variations are available for the calculation of the background intensity values for red and green fluorescence (Rb, Gb) especially with respect to selecting the background region. Among the most popular approaches that utilize the median for the specially-selected region around the spot mask are GenePix, ScanAlyze and QuantArry.

The GenePix package considers the median value of all the pixel values inside the valley region as the foreground intensity value of the spot. The valley region is represented in Figure 1 as four pink rectangular areas surrounding the spot [10]. The background intensity estimation methods implemented in ScanAlyze consider all the pixels that are located outside the spot mask but within the square where the spot lies. This is represented in Figure 1 as the blue square surrounding the red circle. The median of all these pixels is used as the estimated value of the local background intensity of the spot. Finally, the QuantArry method uses the median of every pixel in the area between two green concentric circles in Figure 1 as the background intensity value for that spot [11]. While the QuantArry method uses the median of every pixel in the area between the two green concentric circles in Figure 1 as the background intensity value for that spot [11]. While the QuantArry method uses the median of every pixel in the area between the two green concentric circles in Figure 1 as the background intensity value for that spot [12], [13] and [14].

Background	Four Diamonds	Blue Square & Spot Mask	Two Concentric Circles
BG Calculation	Median	Mean	Median

Table 1 Comparison different background estimation alternatives

From the data collected in Table 1, it can be seen that using the median of the pixels' values in the GenePix region decreases the possibility of calculating an erroneous value because the region is very distant from the spot and will not include any pixel that belongs to the spot. Thus, miscalculation is avoided for the bright pixel. However, estimation inaccuracy may occur in the other approaches, e.g., in ScanAlyze where there is overlap between the foreground and background areas, and hence it is inevitable that the values of pixels belonging to the spot will be included in the calculation.

2.2 Most Recent Background Correction Methods

The usual calculation method for finding the corrected value for the intensity of the spot for a twocolor microarray is that of subtracting the values of the background intensity of the two colors, red and green (Rb, Gb) from the values of the foreground intensity of the two colors (Rf, Gf). This allows the true spot intensity (R, G) to be more accurately evaluated. This is because the observed foreground intensity value is the sum of the background value and the true intensity value of the spot [15] and [16].

The standard background correction method is usually applied by taking the mean of the foreground values and the median of the background values. The background value is then subtracted from the foreground value to define the true value of the spot intensity. Sometimes the background intensity value is greater than the foreground intensity value, and thus the final result is negative, which is illogical. Therefore, many scientists and researchers have attempted to develop more logical and accurate methods [3].

The Kooperberg correction method is one of the best methods. This method uses the mean of both foreground and background values. Subsequently, a process of numerical integration and convolution is used to calculate the value of the two-color intensity for each spot [1]. This method is restricted to GenePix data and software, and it requires human involvement to function optimally.

A simpler method for avoiding negative intensity values was presented by Edwards using a local median of the background values. This method is similar to the standard method, but when the value after subtraction is less than a specific small threshold value, it undergoes a monotonic function. Whereas when it is larger than the threshold value, it can be considered to be the true intensity of the spot [3] and [17].

Another method for performing the background correction is the morph method. This method uses the main value of the foreground intensity values and morphs the background value, which can be done by performing a morphological opening that involves an erosion operation followed by a dilution operation to find the local maximum and the local minimum. Subsequently, the true value can be estimated by subtracting the background from the foreground value [18]. Similarly, the tophat method enhances the image to increase the contrast between the spot mask and the background, so that background intensity is decreased automatically [19] and [20]. The last method considered is that of estimating the value of the background intensity is zero. Thus, the true intensity value is taken as the median or mean of the foreground values of the spot. The result of using this method will be a very high value for each spot with both red and green intensities because there is no subtraction involved. However, this method is somewhat illogical since it is not reasonable to assume that all background spot intensities are zero [3] and [19].

Using the data collected in Table 2, different methods of background correction were compared. The standard method is the simplest method but sometimes the result has a negative value when the background intensity is larger than the foreground intensity, which is not meaningful in reality. The Kooperberg integration method decreases the possibility of error, but it is restricted to GenePix's background values. Edwards has also improved the standard method but in a way that is not restricted to any specific software, and furthermore, the threshold value can be changed according to the spot until there are no negative values. The morph estimate is another approach to finding the background value, but it is more liable to error and it is also restricted to spot software. Finally, the method that estimates the background value as zero might possibly serve for the case of an ideal microarray image, but unfortunately, this ideal is rarely encountered in practice.

3. MATERIAL AND METHODS

Using MATLAB, we developed a code that can extract the intensity for 10 spots as shown in Figure 2. Using only 10 spots instead of the whole microarray slide makes the process easier and simpler especially when comparing the many different algorithms used. In order to define a method which would be more accurate and suitable for this project, a MATLAB code was developed and tested according to the flowchart in Figure 3.

As can be seen from the flowchart, the MATLAB code starts by importing the whole microarray slide image using the command imread. Then, the image is cropped to 10 spots as shown in Figure 2 using the command imcrop. MATLAB usually reads the image intensity as a matrix of pixels. Thus, our image after cropping is 40*95 pixels although it has only 2*5 spots. Therefore, each spot has a size of around 20-pixel diameters. We then calculated the intensity value for each spot according to the method under consideration.

Figure 2. Microarray slide with 10 spot.

Figure 3. Methodology flowchart.

For the standard method, we first calculated the foreground and background intensities by finding the median value of the pixels inside each area. Then, we calculated the spot intensity by subtracting the background from the foreground. This is similar to the Edwards method, but in the latter, there is a threshold point (value = 0) applied after the subtraction process. However, in the top-hat and no-background methods, the foreground and background intensities were calculated by finding the mean value of the pixels inside each area. We summarized the results for each method in six separate tables for ease of comparison and understanding as shown in section 5.

Finally, one method was chosen and used for extracting the intensities of 100 spots as shown Figure 4. An ideal image with 100 spots was used to check the accuracy of the results. This image is shown in Figure 5.

Figure 4. Microarray slide with 100 spots.

Figure 5. Ideal Microarray slide with 100 spots.

4. RESULTS AND DISCUSSION

Almost all the methods, except the top-hat method, show some similarity, especially when we compare the difference between the green and the red intensities for the same spots. The standard and Edward methods have approximately the same intensity values for the same spots, with only 0.5 differences in values for some spots. The no-background method showed higher intensity values for every spot compared to the other methods. The relationship of the intensity value of the spots in the top-hat method with the same spots in the other methods is variable.

Table 3 shows the results for the standard method, where the result is equal to the median of the background values subtracted from the foreground values, without the use of a threshold. This means that some of the spot values became negative when the background value was greater than the foreground value for a particular pixel. However, since there were a median and many other positive pixels on the spot, the negative value does not appear in the final result of the spot.

The no-background method results are shown in Table 4, with values that are greater than the values of the other methods for each spot. This was due to the fact that there was no subtraction step because the background values for each spot were equal to zero. In addition, not all the intensity values are natural numbers due to the division process during the calculation of the spot intensity where the mean value of the pixels located inside the spot mask is taken.

Spot intensity values for the Edwards method are shown in Table 5; they are almost equal to the standard method except that there are differences of 0.5 of the pixel for some spots. This is due to the use of threshold and median values, since negative numbers will be changed to zero, so that they will not affect the final result when the median is used. However, if we use mean values, the difference will be more than 0.5 of the pixel.

Finally, with regard to the top-hat method in Table 6, the difference between this method and the others is variable due to the image enhancement process using the command imtophat in the MATLAB toolbox. In addition, the difference between the green and the red intensities for the same spot is smaller than in the other methods, while from the image we can see that it is much larger.

STANDARD METHOD		1	2	3	4	5

Intensity	Raw 2	25.14	25.34	31.15	44.52	99.54

From tables 3, 4, 5and 6, it can be clearly seen that almost all the methods can calculate and display the intensities, although the values of the intensities are different due to the different background values. In Table 5, the Edwards method used zero as the threshold value and this method also showed a clear, non-zero background value. Therefore, we propose this method as the most suitable for this project.

To check the results of the Edwards method, an ideal-image microarray slide was used, so that the results were accurate and known as well as they have been settled. Matrix 1 shows the results for

the ideal-image intensities shown in Figure 5. The red and green intensities are displayed in separate matrices with elements arranged in the same way as the arrangement of the spots in the slide, with each element in the matrix representing the intensity of the corresponding spot in the image. Similarly, this method was used to extract the intensities for the real microarray slide shown in Figure 4, as an example of a 100-spot image. Matrix 2 represents the intensities of the image spots.

5. CONCLUSION

In this paper, a number of background correction calculations and algorithms were reviewed. The differences and similarities of the existing systems were studied in order to identify the criteria for selecting the best program, the program which gives results closest to the true intensity values. Three methods for allocating and calculating the background intensity values were discussed and compared. These methods were GenePix, ScanAlyze and QuantArry. Five alternative background intensity corrections were applied to a microarray slide image using MATLAB in order to find the most accurate intensity value for each spot in the two-color microarray, and the results compared. Based on the findings, it was concluded that the Edwards method is the best and the most suitable method for correcting background intensity.

ACKNOWLEDGEMENTS

This research was funded by Science Fund, Ministry of Science, Technology and Innovation (MOSTI), Malaysia (2015).
